ABSTRACT
Objective: Breast cancer is a heterogenous disease, and genetic profiling helps to individualize adjuvant treatment. The Oncotype DX is a validated test to predict benefit of adjuvant systemic treatment. The aim of this study is to determine the costs of chemotherapy in government hospitals in Turkey and evaluate the cost-effectiveness of the Oncotype DX from the national insurance perspective.

Materials and Methods: A Markov model was developed to make long term projections of distant recurrence, survival, quality adjusted life expectancy, and direct costs for patients with ER+, HER2-, node-negative or up to 3 node-positive early stage breast cancer. Turkish decision impact study patient data were captured for model reference. In that study, ten academic centers across Turkey participated in a prospective trial. Of 165 patients with pT1-3, pN0-N1mic, ER-positive, and HER-2 negative tumors, 57% had low recurrence score (RS), 35% had intermediate RS, and 8% had high RS, respectively. The overall rate of change in chemotherapy treatment decisions following Oncotype DX was 33%.

Results: The cost of adjuvant chemotherapy in public hospitals was estimated at $3,649, and Oncotype Dx test was $5,141. Based on the cost-effectiveness analysis, Oncotype DX testing was estimated to improve life expectancy (+0.86 years) and quality-adjusted life expectancy (+0.68 QALYs) versus standard care. The incremental cost-effectiveness ratio (ICERs) of Oncotype DX was estimated to be $7207.9 per QALY gained and $5720.6 per LY gained versus current clinical practice.

Conclusion: As Oncotype DX was found both cost-effective and life-saving from a national perspective, the test should be introduced to standard care in patients with ER+, HER-2 negative early-stage breast cancer in Turkey.

Keywords: Early breast cancer, genetic profiling, oncotype-Dx, cost, markov model.

Introduction

Invasive breast carcinoma is the most commonly seen malignancy and leading cause of cancer related death in Turkish women. An analysis of 13,240 patients in the National Breast Cancer Database established within the Turkish Federation of Breast Diseases Societies showed that 50% patients had N0 and 27% had Stage I breast cancer, respectively. Overall, 80.7% of patients had luminal molecular subtype

Despite available data on chemotherapy efficacy in locally advanced and metastatic breast cancer, it is not possible to predict who will benefit from adjuvant treatment in early stage breast cancer based on traditional clinical pathological features. The major pathological and clinical features including age, menopausal status, tumor size, histologic grade, ki 67 proliferative index, estrogen (ER) and progesteron receptor (PR) and human epidermal growth factor receptor 2 (HER-2) expression are commonly used by clinicians to guide chemotherapy treatment decisions; however, in cases with equivocal features, the decision to recommend adjuvant chemotherapy may be uncertain. Furthermore, challenges remain regarding the inter- and intra-laboratory standardization of a number of clinical risk factors.
The emergence of genomics and transcriptomics techniques and the ability to measure various genes led to the identification of tumor-biology based prognostic and predictive determination. The Oncotype DX RS is one of the best-validated prognostic assays and may identify patients who are most and least likely to derive benefit from adjuvant chemotherapy (1, 2).

The Oncotype-DX test is validated for patients with node-negative early breast cancer as well as limited node involvement (pNmic/pN1), pT1 tumors, and the median tumor size was 2 cm. Only 11 (6.7%) patients had micrometastasis in axillary lymph nodes (pN1mic). The model cohort age was assumed to be 49.9 years based on the mean age from Turkish Oncotype-Dx Decision Impact Study cohort (8). In this patient group, 108 patients (65.4%) had stage pN0 and 49 patients (29.4%) had single node positive early-stage breast cancer for an analysis for England and Wales (9). The model made projections of life expectancy, quality-adjusted life expectancy and direct costs, based on recurrence rates for low, intermediate and high-risk patients as well as country-specific mortality data. The risk was adjusted by reference models as demonstrated on Table 1, 2 and 3.

CT: chemotherapy; HT: hormone therapy

As early stage breast cancer incidence is increasing with improved cancer screening methods, with half of breast cancer cases presenting as stage pN0 in Turkey, suboptimal evaluation for treatment planning may lead to many patients unnecessarily exposed to chemotherapy and associated toxicity and may increase health expenses. Besides, patients who may derive a substantial benefit from chemotherapy to prevent distant recurrence may not receive chemotherapy.

In this study, we aimed to evaluate the cost-effectiveness of Oncotype DX in a developing country using our patient population as a model reference.

Materials and Methods

Model overview

The model used in this analysis is generated via local adaption of a Markov model, that was developed in Microsoft Excel, based on an original model by Hornberger, to evaluate the long-term costs and clinical outcomes associated with introducing Oncotype DX testing to inform decisions about adjuvant chemotherapy for patient with ER+, node-negative or single node positive early-stage breast cancer for an analysis. The model made projections of life expectancy, quality-adjusted life expectancy and direct costs, based on recurrence rates for low, intermediate and high-risk patients as well as country-specific mortality data. The risk was adjusted by reference models as demonstrated on Table 1, 2 and 3.

Clinical parameters

To ensure that the modelling analysis was in line with the standard clinical care pathways in Turkey, patients were assumed to receive standard endocrine therapy and chemotherapy regimens in line with local practices evidenced in the Turkish Oncotype-Dx Decision Impact Study and the Turkish Cost-Effectiveness Analysis of Screening in Breast Cancer (8, 10). The model cohort age was assumed to be 49.9 years based on the mean age from Turkish Oncotype-Dx Decision Impact Study cohort (8). In this patient group, 108 patients (65.4%) had pT1 tumors, and the median tumor size was 2 cm. Only 11 (6.7%) patients had micrometastasis in axillary lymph nodes (pN1mic). The
majority (53.5%) of the patients had a ki67 score of <20%, 60.4% patients were considered to have luminal B molecular type. The change in the chemotherapy decision between pre and post RS assay treatment plans was analysed using McNemar's test (Table 1).

In each cycle of the model, the risk of recurrence was evaluated for each simulated patient based on their RS defined category of low, intermediate or high risk as reported for the NSABP B-20 cohort (4) (Table 2). Risk was adjusted based on whether patients were receiving chemotherapy as per the initial recommendations (in the usual care arm) and based on the Oncotype DX Recurrence Score (in the Oncotype DX arm). Non-breast cancer death was captured as a competing risk in the model, based on Turkey life tables (Turkish Statistical Institute) for females in 2013 (11). For patients experiencing distant recurrence, survival was assumed to be 3.3 years (12).

Costs of treatment
In the cost-effectiveness model the costs of endocrine therapy, chemotherapy, adverse events associated with chemotherapy and the cost of distant recurrence were accounted. All costs were taken from Turkey-specific sources as Turkish lira, converted and expressed as dollars in the analysis, using the currency conversion rate as of February 2016 when the data collection was conducted. A summary of cost variables used in the model is provided in Table 3.

All the medicine costs, follow-up costs, mammogram costs and other cost items are taken from Turkish Cost-Effectiveness Analysis of Screening in Breast Cancer (10).

The cost of endocrine therapy is incurred over 8 years, at different rates over the initial 5 years and later 3 years to reflect varying treatment patterns. For those patients receiving chemotherapy, the costs of chemotherapy and endocrine therapy are both incurred in the first year. Based on 4-6 cycles of chemotherapy, there is thus an overlap of costs of approximately 3.5 months.

Costs of all drugs related with treatment and toxicities, costs of follow-up (mammography, ultrasound, biopsy, CT-scans etc.) are taken from Turkish Cost-Effectiveness Analysis of Bahcesehir Breast Cancer Screening Program (10). The cost of chemotherapy evaluated the chemotherapy regimens, number of cycles, doses of chemotherapeutics, concomitant medications used to prevent or treat adverse events, diagnostics etc; the frequency and duration. Adverse events associated with chemotherapy; the cost of screening, diagnostics, treatment and follow-up for adverse events associated with treatment were based on the Turkish Oncotype-Dx Decision Impact Study cohort (8).

Risk of recurrence associated with endocrine therapy and relative risk reduction associated with chemotherapy were both taken from the Paik et al. (4) NSABP B-20 study of Oncotype DX. Local recurrences

---

**Figure 1. Overview of the Oncotype DX cost-effectiveness model structure**
are not captured in the model. The cost of recurrence was generated from Bahcesehir Breast Cancer Screening Program (11).

Rate of non-cancer related death is taken from Turkish life-tables.

**Quality of life**
Quality of life utility scores were based on the published literature. Patients that were in the recurrence-free state and in the recurrence state accrued utility scores. Health utility scores range from death (0) to perfect health (1) and quantify the particular health situation. Published utility scores were used, with a disutility of 0.07 was applied to capture the health-related QALY (14). and annual utility scores of 0.60 and 0.78 were applied for patients with and without recurrence respectively (15, 16) Health utility associated with one year in the recurrence free state was assumed to be the same during and after endocrine therapy (16).

**Endocrine therapy costs**
In the model, all endocrine regimens were considered, consistent with current practices in Turkey: tamoxifen for 5 years, AI for 5 years, tamoxifen and AI sequential use and extended adjuvant treatment beyond 5 years.

The probability of treatment with each regimen was derived from the Turkish Cost-Effectiveness Analysis of Screening in Breast Cancer, with pharmacy costs for all interventions, follow up and mammograms were taken from the SGK Appendixes. In the model the annual per patient cost of treatment and follow up was calculated to be $256.5 for the first 5 years and $289.6 for years 5-8.

Adverse event rates and costs for endocrine therapy were not included in the model.

**Chemotherapy costs and adverse events**
The chemotherapy regimens, number of cycles, doses of chemotherapy, concomitant medications used to prevent or treat adverse events and diagnostic tests etc were taken from Turkish Oncotype-Dx Decision Impact Study cohort.

Chemotherapy-related adverse event rates were generated from Turkish Oncotype-Dx Decision Impact Study cohort (Table 4). The majority of costs associated with chemotherapy are due to adverse event and monitoring rather than the acquisition costs of chemotherapy agents.
The total cost of chemotherapy drugs, administration and monitoring was $1436.07 ($507.7 + $432.3 + $495.9).

Sensitivity analyses
A series of one-way sensitivity analyses were performed to identify key drivers of model outcomes. Most clinical and cost parameters inputs the model were varied by +/- 25%. ICERs were reported for all one-way sensitivity analyses.

Results

Base-case analysis
Oncotype DX was projected to cost an additional $1.492 per patient compared with current clinical practice over a 30-year time horizon ($5.141 versus $3.649) (Table 5). The increase in costs was associated with an improvement in life expectancy of 0.86 years (24.84 years versus 25.70 years) and an increase in quality-adjusted life expectancy of 0.68 QALYs (19.26 QALYs versus 19.94 QALYs). The incremental cost-effectiveness ratio (ICERs) was estimated to be $7207.9 per QALY gained and $5720.6 per LY gained for Oncotype DX versus current care to $7971.72 per LY gained. This was due to competing mortality, which meant that patients were not alive long enough to accumulate the full benefit of Oncotype DX testing. In contrast, reducing the baseline age improved the cost-effectiveness of Oncotype DX ($5213.7 per LY gained).

Discussion and Conclusion
Contrary to developed countries, the rate of breast cancer incidence and mortality has been increasing in Turkey and other developing countries due to changing life style, ageing, increase in population size and mammography screening (17). Breast cancer incidence has more than doubled in last two decades in Turkey (1). In our breast cancer registry database, nearly half of the patients had node negative disease and 76.9% had ER positive breast cancer at diagnosis, making these patients good candidates for molecular testing to potentially spare them from unnecessary adjuvant chemotherapy (1). Overtreatment is a big problem due to chemotherapy toxicity and its cost to breast cancer patients (18). Gene expression profiling assays may provide an emerging paradigm to predict chemotherapy benefit based on expression levels of specific tumors. Several multigene assays are currently available for early breast cancer patients, of which Oncotype DX has the most compelling evidence of adding value to standard prognostic factors regarding the benefit of adjuvant chemotherapy for patients with early breast cancer (2).

The MINDACT trial revealed that Mammaprint (70 gene signature test) may identify subsets of patients who have a low likelihood of...
distant recurrence despite high-risk clinical features. In this trial, 6693 women, approximately 80 percent of whom had lymph node-negative disease, underwent risk assessment by clinical criteria (using Adjuvant! Online) and by the 70-genetic profile. Patients with discordant clinical and genomic predictions were randomly assigned to receive or not receive adjuvant chemotherapy. Among patients in the intention-to-treat population who had a high clinical risk of recurrence but a low risk by Mammaprint, a non-significant benefit of chemotherapy with respect to distant metastasis-free survival (DMFS) and a significant benefit of chemotherapy with respect to DFS were seen (19).

The TAILORx trial was designed to determine whether Oncotype DX that analyzes the expression of genes that are associated with risk of recurrence among women with early stage breast cancer could be used to assign patients to the most appropriate treatment choice. In the lowest risk group, the TAILORx trial provided prospective evidence that patients with RS 0-10 may be spared chemotherapy. Among these patients who were uniformly treated with ET, rates of distant recurrence at 5 and 9 years were <1% and 3% respectively. Furthermore, adjuvant endocrine therapy and chemoendocrine therapy was shown to have similar efficacy in women with hormone-receptor-positive, HER2-negative, axillary node-negative breast cancer who had a midrange 21-gene recurrence score (RS 11-25), although benefit of chemotherapy was found in some women 50 years of age or younger (20).

The precision medicine achievable via the use of molecular analysis for early breast cancer patients has been shown to change treatment recommendations. Oncotype DX testing was associated with a notable change in treatment recommendations based on the data reported by Holt et al. (13), with approximately half of all patients originally recommended chemotherapy being recommended endocrine therapy after Oncotype DX testing. In our study, overall adjuvant treatment decisions changed for 33% of patients after Oncotype Dx RS results were discussed in multidisciplinary tumor conference. The present study is the first multicenter analysis to demonstrate cost-effectiveness of Oncotype DX in Turkey using a Markov model. Real-world patient data was used in the model based on the Turkish Oncotype-Dx decision impact study (8).

In several developed countries, Oncotype DX cost-effectiveness has been demonstrated in the early stage breast cancer setting. All studies concluded that Oncotype DX has an ICER less than $100,000 per QALY, however the results were disparate with each other (21).

A study which looked at use of the test in a community “real-world setting,” found that the likely cost-effectiveness ratio for Oncotype DX testing was higher than the ratios for the most commonly accepted diagnostic and preventive interventions. Their simulation model compared 25-year incremental costs and quality-adjusted life-years (QALYs) for Oncotype DX use in the community from 2005 to 2012 with costs and QALYs of usual care in the time period before testing (2000 to 2004). The patients who underwent testing were younger and were most likely to have stage I than stage II disease. Patients who underwent testing and who were younger than age 50 years had lower chemotherapy rates than patients in the same age group who were not tested (53.0% vs 63.6%). In contrast, older patients who were tested had higher rates of chemotherapy compared with the untested cohort (age 50 to 64 years: 36.5% vs 30.8%; age ≥ 65 years: 17.6% vs 8.2%) (22).

In a recent analysis reviewing multiple clinical studies simulation models, demonstrated that cost-effectivity studies has a wide range of heterogeneity in terms of model structure. Some studies did not use the real-world RS distributions and rely on database, some did not evaluate the patients’ risk status independent of Oncotype DX. When cost of chemotherapy were used in simulation models, treatment related toxicity were ignored in some studies. Despite the heterogeneity of these trials, the simulation model revealed that the problematic issues that were identified in the analyses do not change the conclusion that

ICER: incremental cost-effectiveness ratio
Oncotype DX is cost-effective for the clinically intermediate or high-risk group but not for the clinically low-risk groups (21).

Cost-effectiveness analysis (CEA) is increasingly important in public health decision-making especially in low- and middle-income countries. When cost-effectiveness is evaluated for developing countries, willingness to pay may be at lower ICER thresholds, with many health interventions deemed cost-effective but not accepted as affordable by local authorities. This multicenter prospective trial showed that Oncotype DX is cost-effective and improves QALY in a developing country model. By leading to changes in adjuvant chemotherapy decision and modifying long-term risk of distant recurrence, Oncotype DX was projected to improve life expectancy (+0.86 years) and quality-adjusted life expectancy (+0.68 QALYs) versus standard care. The incremental cost-effectiveness ratio (ICERs) of Oncotype DX was estimated to be $7207.9 per QALY gained and $5720.6 per LY gained versus current clinical practice.Sensitivity analysis showed that the cost-effectiveness of Oncotype DX testing was not sensitive to variations in several clinical and economic parameters. In all sensitivity analyses, Oncotype DX was associated with ICERs in the range that would be considered cost-effective by commonly quoted standards.

Oncotype DX was estimated to improve quality-adjusted life expectancy versus standard care, due to chemotherapy avoidance in low-risk patients in addition to survival benefits in high-risk patients. In this analysis, data of patients who were recruited from state hospital and academic centers were taken into account where all costs are reimbursed by general health insurance. However, there are considerable amount of patients who apply to private hospitals and take the Oncotype DX with their personal expense. If it was possible to add these patients’ data to the analysis, we believe that the cost-effectiveness of the test would be more favorable.

Oncotype DX provides additional information to improve personalized chemotherapy treatment in early stage breast cancer patients and changed adjuvant chemotherapy treatment decisions in 33% of patients. The test was found cost-effective from a national perspective, with improvements in quality of life and may be introduced to routine clinical practice in patients with ER+, HER-2 negative early-stage breast cancer in Turkey.
